Acknowledgements

The preparation of this paper has been the result of the kind cooperation of my faculty advisors Dr. L. Russwurm and Professor G. Priddle without whose generous assistance and constructive suggestions this paper would not have been possible. In addition I would like to thank all the members of the Geography Department at Waterloo University College for their insights and ideas relating to the study of Geography and geographic research.

I would also like to thank the Planning and Recreation Departments of the City of Windsor for their kind assistance and all the many other people directly or indirectly connected with the final presentation of this paper.

CHAPTER 1

INTRODUCTION

"The type of Geography which admits the importance of quantification and the appropriateness of statistical methodology, but always as servants and not as masters, would appear to be the best answer the profession can furnish to the embarrassing questions which have arisen during the current debate in academic circles regarding geography's right to be included in the curricula of institutions of higher learning."

____ William Warntz

As a geographer interested in the problems of location and behavioral models relating to man's reaction to space, my purpose in this paper is to establish a quantitative approach to the analysis of a specific location problem as applied within the field of recreation analysis.

With regard to the analysis of recreation behavior, many areas of human behavior need to be considered for the investigation and understanding of outdoor recreation habits extendy far beyond the realm of any one specialized field. Much of the research yielding important insights might not at first appear to be geographically important since it is carried on by economists, sociologists, demographers, political scientists and so on. Moreover, one of the most important contributions that could be made but appears to have been neglected to a large degree is the geographic problem of determining the proper location of recreation facilities.

Performance in the past seems to have made it clear that the process of planning by spurts and sudden crisis can achieve little. We need new tools and techniques not only to cope with new problems, but to expand and deepen our knowledge of recreation as a systematic form of behavior. In this way it might be possible to develop effective behavioral models for recreation; thus helping recreation planners to decide when to act, where to act and how to act in response to a particular stimulus. Consequently, I have defined in a general"systems" framework, those terms within which the essential characteristics of a recreation problem can be identified and features of a solution explored. The development of this systems approach is followed by a behavioral model designed to combine the relevant variables of the system into a meaningful and useful instrument to be used in the planning and location of outdoor recreation facilities. The model in its final form is specifically designed for estimating the optimum location of the outdoor swimming pool.

Although the approach taken relies heavily upon methods used in analyzing the optimum location of retail outlets, it differs in its application by the consideration of a "double universe". The meaning and significance of this double universe appears to be an important improvement over the approach taken by some marketing geographers and shall be discussed at further length later in the paper.

Finally, it might be noted that in many cases, exact pertinent consideration of the variables involved in recreation planning are merely touched upon briefly, not because they are trivial, but because

they may perhaps deserve serious examination in their own right which would be beyond the scope of this paper. Consequently, I have relied heavily upon those authors who have recently contributed to a series of articles published by the Outdoor Recreation Resources Review Commission, Washington, D.C. and in particular, Perloff and Wingo whose appreciation of systems theory has contributed immeasurably to the "system" I have designed for recreation planning.

CHAPTER 11

THE ESTABLISHING OF A "SYSTEMS" FRAMEWORK FOR THE PLANNING OF OUTDOOR RECREATION FACILITIES

In an attempt to understand the problems inherent in recreation planning it might first be advisable to classify and place in perspective those elements that appear to be relevant to the analysis of a particular recreation problem. One approach is through the analysis of systems theory which deals with sets of objects or factors, these objects or factors being the parts or components of the system. Any recreation activity or group of activities can be viewed as a system with sub-systems being a part of larger systems.

The value of general systems theory is that it shows a concern for theoretical formulation and model building, and the use of probabalistic rather than deterministic solutions. ¹All the difficulties involved in an analysis of recreation perhaps argues for the need for a new planning framework — a system which brings into perspective the recreation of urban populations, the evolving needs and demands, and the requirements and potentialities involved in supplying these needs.

h

l Perloff and Wingo enter into a discussion of the application of systems theory and recreation in their article <u>Trends in American</u> <u>Living and Outdoor Recreation</u>, Outdoor Recreation Resources Review Commission study report no. 22 (Washington, 1962) pp. 81-100.

Two steps then, need to be taken: first to investigate the nature of the elements of the system _-populations, recreation activities, and the facilities for these activities, and second to explore the interactions between them.

A Population Groups as Elements:

The first step is to disaggregate the population into groups which are reasonably homogenous. These outdoor recreation groups are the basic units of the system, and are so drawn as to exhaust the population. The population is broken down by age, sex, education and socio-economic status. Under these conditions, any changes in the group behavior is then achieved by the process of assigning the members of a population to the outdoor recreation groups through estimates:

(a) of the characteristics of new population increments and
(b) of the probabilities that individuals will shift among the outdoor recreation classes in the interim (changes in age, education
and socio-economic status).

1 Age

One's age or position in the life cycle has a substantial influence on what outdoor recreation activities he is likely to engage in. Young single persons are predisposed toward more active and more challenging activities while elderly retired couples frequently seek reasonably passive but gregarious recreation activity. In this sense, where one stands in the life cycle has an important

effect in setting out the bounds within which recreation behavior is likely to take place. As an example, an activity such as swimming greatly decreases with age as shown in the accompanying graph, and thus there is a specific age group that swimming as a form of recreation activity is most appealing to. Any shift in the age structure of the population will cause a net change in the popularity of swimming.

2 Sex

3

The recreation propensities of males and females differ to the extent that males prefer more active and challenging recreations than do females who are in most cases more predisposed towards passive and social recreations.

3 Socio-economic Status

Socio-economic status, meaning wealth and position in the community, is equally obvious as a variable in how people make decisions about their use of leisure time. This variable has a number of dimensions--rich people can simply afford more expensive forms of recreation than the less affluent. There is also a class effect--certain recreations have prestige associations which influence recreation behavior. The influence of income on recrestion in general can be seen by examination of the accompanying chart. The number of retreation days per person greatly increases

· A start

'-₆ '

,

a contra de la contr

6 3⁶ *

đ

with income. This effect is gradually changing however, with the average worker getting continually increasing wages and more vacation days every year. The forty hour work week will soon be a thing of the past. 4 Education and Cultural Background:

Education is closely bound up with socio-economic status and ethnic origin. People of different cultures and different incomes prefer different recreations. By way of example, polo and soccer are activities pursued in some European and Latin American countries but followed only negligibly in North America. Where a large immigrant population is present their recreation patterns and habits are readily apparent and must be accounted for.

B Activities as Elements:

The type of activity under consideration often determines who participates, when, where, and how much. Whether it is an active, passive, group or family activity, it has the role in the system of linking the demand side of the population to the supply side consisting of any of the facilities which policy provides. It is in the understanding of the demands of the population that the type of activity needed is recognized. The supply side of the system is balanced off with the type of facility provided.

² For a more detailed discussion of the effects of age, socioeconomic status, sex and education on recreation behavior refer to Perloff and Wingo, <u>Urban Growth and the Planning of Outdoor Recreation</u> in O.R.R.R.C. study report no. 22 (Washington, 1962) pp 85-87.

C Facilities as Elements:

Facilities for outdoor recreation have several key characteristics which influence the manner in which the system operates.

1 Specialized Facilities

A facility may be highly specialized in use so that one, or at best a few facilities permit several activities to be enjoyed concurrently by different users.

2 Multiple Purpose Facilities

A facility might be multiple purpose in the sense that it is arranged to permit a number of specialized and unspecialized activities to be carried out simultaneously.

3 Size of the Facility

Whatever the resource endowment of the facility, simple size or area has an important relationship to capacity for most activities. Whatever the facility, whether it be a local swimming pool or a regional park, the physical size of the facility in question often determines how many people will participate.

4 The Accessibility Factor

The accessibility of a recreation facility often determines the utility or frequency of patronage. The farther away a facility is from the user group, the less the frequency of patronage is likely to be. How often does a person go to a nearby regional park instead of a park like Banff in Alberta? Of course a lot depends on the recreation experience to be enjoyed but physical distance or accessibility can be viewed in terms of the time and money costs associated with travel. This is particularly true in terms of travelling to duplicate alternative recreation sites. Physical distance thus becomes a friction factor in terms of usage or utility. 5 The Competition of Duplicate Facilities

The competition of similar facilities is an important consideration when attempting to balance off the supply side of the problem. In an attempt to analyze consumer ' behaviour one must consider all potential facilities simultaneously. Given several comparable facilities all other things being equal, the recreationist will use the nearer more frequently—or to the exclusion of— the more remote.³ Although this relationship seems quite simple, it is one of the most important factors to consider in the establishment of a recreation system for future planning.

D The Geographic Location Factor

The location factor is bound up with all the elements of the system previously discussed. Location in its broadest sense has a special set of effects depending on the level of interest. At the regional level, uniquely local patterns in the use of leisure are

3-161d.

perhaps apparent. At another level, the influence of location results from conditions of accessibility or distance. Location related to the distance concept determines the time, money and inconvenience costs of gaining access to facilities depending on what population group you are dealing with. In effect, location determines the impact of competition, the friction of distance on the habits of the consumer, and the decision to develop additional facilities.

Although location does not fit the role of an input, it is so critical a factor affecting the ability of a facility to produce services valued by a recreation clientele that it should perhaps lie at the center of the system. Location affects the performance of a facility because distance influences the recreation decisions of the consumers.

. 1

A systems analysis approach to a problem requires a focus on the relationships which connect the elements of the system together and which are pathways by which changes are communicated among the elements. If the problem is seen to be one of relating a set of demand conditions to a set of supply conditions, these interactions stand in the place of the market. In the accompanying diagramatic expression of the system developed for recreation, interdependence is directly apparent in the complex array of outdoor recreation demands, activities and facilities.

All outdoor recreation facilities are tied together whereby changes tend to have impacts on many or all of the factors in the system. The facilities turn out specific products at given locations. Further, the system includes a set of consumers with propensities to engage in cartain kinds of recreation, hudgets in both time and money, knowledge

of alternatives, and an inclination to act rationally to maximize their net satisfactions.

It is the behavior of consumers which powers the system, the consumer being at the fulcrum of supply and demand. The Effect of Changes Within the System:

If in the short run one facility is expanded, this expansion will set in motion a wavelike set of impacts. In the first instance, those facilities for which it is an easy substitute will experience a reduction in the intensity with which they are used. This impact will be spread throughout the system of facilities until an equilibrium is achieved in which new patterns of attendance are once again established. In the same manner, changes are transmitted throughout the system when the activities or populations experience changes. The system is thus seen as an expression of varying conditions, each condition having an effect on the other and revolving around the problem of geographic location. Now that the key elements of the system have been identified it is now possible to establish a method or model for planning such that the kinds and levels of performance that are needed might be achieved. It might however, be advisable to first explore the behavioral approach to recreation planning in the light of present marketing methods, and trends in the business world.

CHAPTER III

THE BLHAVIORAL AIPROACH TO RECREATION PLANNING IN THE LIGHT OF METHODS PRESENTLY USED BY MARKETING ANALYSTS

Having identified the relevant variables in recreation planning and having placed them in a workable framework in order to demonstrate their inter relationships, the next step is to develop a meaningful expression of the system as applied to the recreationist's behavioral pattern. Behavioral patterns have been closely studied by market analysts in their attempts to demonstrate the importance of location in the travel patterns of shoppers. As such, they have made significant contributions to the understanding of the behavioral approach to other forms of planning. The gravity model approach is a case in point. The Gravity Model Concept:

One of the first to formally apply a behavioral approach to marketing was William J. Reilly. Using Newton's law that "the attraction between two masses is directly proportional to the products of their masses and inversely proportional to the squares of the distance between them", he attempted to apply the concept toward determining the relative retail pulling power of two competing cities on an intervening area. His hypothesis was that, "two cities attract retail trade from an intermediate town in the vicinity of the breaking point approximately

in direct proportion to the population of the two cities and in inverse proportion to the square of the distance from the two cities to the intermediate town."⁴ Reilly's study was published in 1929 and has come to be known as "The Law of Retail Gravitation". Since then a number of empirical studies have been conducted using his basic model particularly in the field of marketing research.⁵

The shortcomings of many of the behavioral models based on the gravity concept of Reilly was that he had never intended to quantify the movements of persons as market research analysts have attempted to do. However, the concept itself is well worth exploring for on the demand side of recreation, the counterpart of accessibility can be viewed as a so called "gravity model" in which is incorporated the tendency of demand for a service to vary inversely from its distance to the consumer.

The Model of Huff:

A second contribution to the understanding of location related to behavioral patterns was the model developed by D. L. Huff, designed to establish the optimum location of shopping centres. The basic form of his model is more applicable to the understanding of planning for recreation facilities because:

1. The prime interest of the planner is the maximum satisfaction of the consumer who lends himself to behavioral studies and patterns.

4 Reilly, W. J., The Law of Retail Gravitation, New York, 1931, p.4. 5 For a straightforward and clear explanation of the gravity model concept read the article by P. D. Converse, <u>New Laws of Retail</u> <u>Gravitation</u>, Journal of Marketing, vol. 14, 1942. It must equip the system with a feed back to
allow for changes in the components of the system.
In other words the model must be easily adapted to
changing conditions in the system through time.
 It must make full use of the internal dependencies
of the system whereby when one input changes the other
inputs also change in response to the original stimulus.
 The model must be simple, easily interpreted,
reasonably accurate, and readily adaptable to a variety
of recreation problems, particularly with regard to the
location problem.

5. Finally, the model must be an imitation or simulation of real world processes so that the predictive abilities afforded by the basic model can be extended even further by incorporating additional variables.

Inputs of The Basic Model

Thus far, only the distance factor has been mentioned as one variable that can be adapted to a gravity model concept. In developing a basic model of consumer reaction to space, the model must also estimate the likelihood of a consumer patronizing a particular recreation facility by taking into consideration all potential facilities simultaneously. In other words, when a recreationist is faced with the alternative of similar recreation facilities, the decision to go to one particular facility is B result of the consideration of all the facilities in question. This input represents the

6 mid p.5

competition factor which must be considered in any marketing approach. Finally, the model must include an expression of the physical size of the facility in question as size is a determinant of potential utility in terms of how many people can actually make use of it. Many of the other inputs of the system can be included in the basic model depending on the type of recreation under investigation. However, the elements of size, distance and competition represent the primary inputs of the basic model. Again, depending on the level of interest, additional variables can be included.

The Basic Gravity Model For Recreation Planning:

Huff's basic hypothesis is: "The value of a shopping center to a consumer is inversely related to the effort and expense involved in getting from the consumer's point of origin to a given shopping center"? This basic relationship for purposes of recreation analysis might be stated: "The utility of a recreation facility or the value of the facility to the consumer is directly proportional to its size, inversely proportional to the distance from the consumer's travel base and inversely proportional to the competition of similar recreation facilities". Expressed mathematically, it takes the form:

$$P(eij) = \frac{\left(\frac{S_1}{D_{1j}}\right)}{\sum_{j=1}^{n=1} \left(\frac{S_1}{D_{1j}}\right)}$$

7 Huff, D. L., <u>A Probabilistic Analysis of Shopping Center Trade</u> <u>Areas</u>, Land Economics, Vol. 39, 1963, p.86

where:

P(cij)	= the probability of a consumer at
	a given point of origin i travell-
	ing to a given facility j
sj í	= the size of the facility devoted
	to a particular class or type of

recreation

Dij = the travel time or physical distance that is involved in getting from the consumer's travel base i to the facility under analysis j. (Travel time can be associated with cost or the expense and inconvenience that is perceived to be involved in travelling to various recreation sites).

 $\sum_{j=1}^{n-1} \left(\begin{array}{c} \underline{Si} \\ \underline{Dij} \end{array} \right) = an expression of the alternatives that$ a recreationist has in his decision totravel to one particular facility instead of perhaps several others thatare similar. It represents the competition factor either in terms of multiple purpose or single recreation typeclasses.

For purposes of illustration, let us assume that a recreationist is equal distance from two swimming pools that are comparable in size

19

:

with all other factors being equal. The probability of him going to either facility should be 50%.

Thust

P(cij) = ?
Sj = 5000 square feet in both cases
Dij = 1 mile in both cases
j = 2 swimming facilities

Substituting In The Equation:

$$Pcij = \frac{\frac{5000}{1}}{\frac{5000}{1}, \frac{5000}{1}} = .50 \text{ or } 50\%$$

Although this model as it exists does estimate the correct probability under the circumstances described, it's main shortcomings perhaps lay in the misconception of the "single universe" concept which assumes conditions to be constant throughout the study area. It is very unlikely that the relationships described hold true with each subsequent unit of distance. As such it is likely that the impact of distance creates what might be called a "core" user group and a "peripheral" user group which represents a double universe concept. The relationships described in the equation might hold true in the core user group but might change with the impact of greater distances in the peripheral user group. If this is true, separate equations must be developed for each universe with additional variables included to account for any changes that might occur. This appears to be the basic shorteoming of the Huff type model and it is quite likely that swimming pools as well as shopping centers have a somewhat definable "core" of patrons and a "peripheral" market area that cannot be assumed to exist under the same conditions. With this in mind, the final model must be altered to take into consideration differing conditions if they exist. Two different sets of conditions require two equations if the model is to be realistic in its assumptions.

However, this basic type of gravity model can be developed into a reliable model for recreation area analysis partly because it contains the three main features of the system: the inputs of size distance and competition. It brings supply and demand together and the effects are brought out by the consumer and his propensity to use a particular recreation facility.

Because people are seen as possessing characteristics which are associated with their recreation behavior, the populations of the "system" can be broken down into groups, homogenous in large degree and exhibiting consistent recreation habits. Depending on the type of recreation faoility under investigation, the populations can be classified. For example, the demand at any one moment for a recreation type classified by age can be found by summing the recreation propensities of this particular age group.

One important advantage of the model is that it should estimate the "likelihood" of a consumer using alternative recreation facilities in terms of demand gradients (probability values) radiating outwards from the facility under investigation. By adding up all of the consumer demand potentials geographically, a surface potential demand on a local, -regional or national landscape is possible. The demand map can then be

re-adjusted to incorporate a number of additional features of the system allowing for reliable predictions for allocations of consumer demand, location of facilities, the size of facilities and so on.

Operating as a system, changes in demand should become a function of all the other variables which directly or indirectly are a part of the basic model. These changes can be analyzed and different classes of activities planned ahead of time to cope with these future estimates.

Application of the systems approach and the behavioral approach to a specific recreation problem shall be analyzed in the next chapter in the hope that the accuracy and performance of the method shall serve as an index to its potential value as an instrument for future recreation planning and analysis.

CHAPTER 1V

APPLICATION OF THE SYSTEMS BEHAVIORAL APPROACH TO A SPECIFIC RECREATION PROBLEM

The model thus far developed is incapable of estimating the total number of people that might be expected to attend a given outdoor recreation facility partly because of the limited number of variables that have been incorporated into the model. The next step is to analyze an existing system of recreation facilities in an attempt to identify from the "system" already developed, other relevant variables.

To accomplish this, I have chosen an existing system of outdoor swimming pools in the city of Windsor partly because the necessary information was readily available and partly because of my associated experience in this type of recreation activity. It was necessary to assume that one particular swimming pool (Lanspeary), was the subject pool under analysis in the hope that the information gained would be relevant in the final development of the behavioral model. Finally, it is hoped that the end result will be an accurate account of the number of people that would use the pool during an average week without referring to the actual attendance data until necessary for comparison of results. Its usefulness as a location model is bound up by its ability to predict attendance at a specific location in terms of the many variables that might be involved. If this is accomplished the approach used shall have more than justified itself.

The Approach

Step 1:

Selection of the Necessary Variables from the System

The first necessary step in any recreation problem is to define the relevant variables so that an accurate analysis might take place. The various interactions of these variables are readily apparent by examination of the diagramatic expression of the system. The following factors were chosen from the elements:

A Activities as Elements

The type of activity under analysis is swimming. This represents the demand side of the system.

B Populations as Elements

The population that takes part in this type of activity is basically determined by:

1_age - Having worked with the recreation department in the city of Windsor it is known through experience that the largest user group is probably between the ages of 6 and 19.

2 sex - There appeared to be no difference between a male or female tendency to use this type of recreation facility.

3 education and socio-economic status - At first glance these variables did not appear to influence a person's tendency to make use of a swimming pool. However, in order to be sure, socio-economic status was taken into consideration through the analysis of an "income" effect. **C** Facilities as Elements

The relevant variables to be considered in the supply side of the system are:

- 1. The competition of duplicate recreation facilities.
- 2. The accessibility of the subject swimming poel under analysis (distance factor).

3. The size of the subject swimming pool.

The facility is specialized and used only for the purpose of swimming.

Step 2:

Testing The Variables Using Multiple Correlation Analysis

In order to be sure that the correct variables were chosen from the system, a multiple correlation analysis of the chosen variables was undertaken. The following procedure was followed:

1. Selection of An Effective Sample Group -

During the period of July 18-25 every sixth person was interviewed to determine where they lived, their age and how oftem they used the subject pool. The address of each user was plotted on a base map with a scale of 1 to 8000 and the distance was measured to give an accurate estimate of this variable. Straight-line distance was used because of the impossibility of establishing what the actual routes of the users might have been.

.

ł

.

SET OF EAST DISEA OF BENELL FOR

Upon plotting the location of each user it was interesting to note that approximately 57 per cent of the user group was within 2500 feet from the facility with the remainder coming from various areas of the city. This indicated the probable existence of the core and peripheral user group previously discussed and the necessity of following a "double universe" approach. The total number of interviews taken was 202 with a sample fraction of 1/6. The following dot map is a 2/3 reduction of the original base map.

2. Consideration of the Income Effect -

To take into account a potential income effect, the base map previously developed was placed over a municipal census tract map showing income by census districts for the year 1965. It was found that the greatest usage was enjoyed by the lower income proups. By referring to the accompanying map it can be seen that there were no users in the census district with the highest income and relatively few users in the districts of income 5,038 dollars and 5,169 dollars. However in the district with the lowest income of 3,790 dollars there was a large user group even

though they were a greater distance from the swimming pool than the higher income groups.

There is a problem in assuming an income effect in that individuals sampled could be low income individuals of average income groups within the census tract under analysis. However, it is quite possible that families with higher incomes have more alternatives for recreation and enjoy a greater variety particularly in the form of summer vacation trips. The effect of this variable will be estimated in the correlation analysis.

The data collected by the 202 interviews appeared to provide a meaningful base by which a statistical comparison could be made between the effect of distance, the effect of income and the effect of age on the frequency of patronage.

3. The Multiple Correlation Analysis -

With the variables selected the next necessary step was to determine whether the correct variables had been chosen and to estimate their degree of association. A trained recreation planner who is well aware

of the recreation scene and knows that he has selected the relevant variables could quite possibly eliminate this stage of the analysis.

The 202 interviews and resulting tables were broken down into 16 categories corresponding to the sixteen census districts used in the income analysis. These 16 units were chosen because they were the only units that provided detailed income data which was necessary to complete the analysis. The following symbols were used:

X1 = frequency of patronage.

X2 = the average distance in feet that the

population of the statistical unit in question had to travel to make use of the facility.

X3 = the average income in dollars.

٠, ·

. :

X4 = the number of persons between the ages of 6 and 19 that make use of the swimming pool. (It was found from the sample that approximately 95% of the people that made use of this swimming pool were within this age group.)

Table 1 is the table developed from the raw data and upon close examination it can be seen that the frequency of patronage is largely dependent upon the distance factor. The income effect is not readily apparent but the number of people between the ages of 6 and 19 in each statistical unit does show a strong relationship.

Table 2 provides the computations of the squares products and sums for measures of relationship between the frequency of patronage and the three independent variables for the sixteen census districts. The data was tabulated by a 1620 computer and the following results were recorded:

(a)	Explained Variation	-	4323.3329
(b)	Unexplained Variation	30	1226.4171
(c)	Standard Error of Estimate	a	9.4419
(d)	Coefficient of Determination	-	. 7429
(e)	Coefficient of Correlation	a	.8616

The distance factor accounted for approximately 52 per cent of the variation, the income effect accounted for approximately 5 per cent of the variation and the number of people within the specified age group accounted for 25 per cent of the variation. The remainder represents the unexplained variation.

The correlation coefficient was tested to see whether or not a chance occurrence of significant magnitude had occurred as a result of a poor sample size or errors made in the data analyzed. It was found that the percentage probability that the coefficient of .8616 could have occurred by chance was less than 0.1 per cent. Thus, the analysis and the variables chosen were highly significant.

To summarize:

1. Age - The greater the number of people between the ages of 6 and 19, the greater the frequency of patronage.

2. Distance - The closer the user is to the swimming pool the more frequently he is likely to use it.

÷.

\$

There is also a peripheral and core user group each of which is to be recognized by separate equations in the final model.

3. the income effect - The lower the income of a user, the greater is his tendency to use the facility.

In addition, it is accepted that the frequency of patronage should be directly proportional to the size of the facility and inversely proportional to the competition of similar facilities as assumed by the basic gravity model approach.⁸

Step 3:

-

Establishment of Functional Statistical Units

Divide the study area into small statistical units (a grid). The standard census districts used in the multiple correlation analysis were found to be too general and too large. The greater the number of statistical units in the grid, the more refined is the analysis. Consequently, 250 sub wards of the municipality were used. The income, numbers and ages of the population residing in each of the units was then recorded.

Step 4:

The Size, Competition and Distance Factors

Determine the size and location of all the competing swimming pools \checkmark within the study area. There are three additional swimming pools other than Lanspeary. Atkinson pool is situated in the north-west part of the

⁸ Huff, D. L. <u>A Probabalistic Analysis of Shopping Center Trade Areas</u>, Land Economics, Vol. 39, 1963 pp. 87-89

city, Prince Road in the extreme west end, Herman in the south-east and Lanspeary in the center. The size of each pool was expressed in terms of square footage of swimming area. The distance of each statistical unit from each swimming pool was calculated in feet.

Step 5:

Establishing the Surface Demand-Potential Map for Swimming The basic gravity model takes the form:⁹

$$P(eij) = \frac{\left(\frac{Si}{Dij}\right)}{\sum_{j=1}^{n=1} \left(\frac{Sj}{Dj}\right)}$$

or:

"the probability of a consumer at statistical unit i travelling to swimming pool j F(cij), is directly proportional to the size of swimming pool j (sj), inversely proportional to the distance of statistical unit i to swimming pool j (Dij), and inversely proportional to the competition".

The swimming pool under analysis in this case was Lanspeary (j). The number of pools was four. The model was applied to each of the 250 statistical units using a 1620 computer system and Fortran statements.

9 Ibid p.87

ł,

The appropriate values were then plotted in the center of each statistical unit and isolines of probability were drawn up to give a geographic representation of the surface demand potential as shown in the following map. It is interesting to note in the accompanying map that the isolines form irregulat) patterns around the subject pool. The further away the isolines are from the center, the greater the spacing is to the next succeeding line. This can probably be accounted for by the distance factor. The isolines also appear to "sweep" away from the other swimming pools towards Lanspeary which is likely due to their own drawing power of the competition factor. The most important thing to note is that the 70 per cent probability line is very closely associated with the core user group established in the original sampling. Outside this core the probability values assume more extreme and irregular patterns. Finally, it is important to observe that there are no rigid boundary lines between market areas, a concept that many recreation planners have relied upon in the past.

Step 6:

Accounting for Irregularities in the Pattern of Demand

by the Inclusion of Additional Variables

At this point in the analysis, the irregularities of the surface demand potential and any other variables that are relevant to the recreation problem must be accounted for.

1 The core user group -

With regard to the recreation situation under investigation, it had been established that there was an irregular pattern between the core user group and the outside user group. The core user group appeared to satisfy the conditions set forth in the basic equation as shown by

the previous demand potential map. To find the total attendance of this core group during an average week, multiply each probability value in each statistical unit by the number of people in the user group. The resultant value is then multiplied by the average weekly attendance of the core user group. To illustrate:

$$j = (P.S.Fn)$$

where:

- j = the total attendance of swimming poel
 j inside 2500 feet.
- P = the probability values obtained by the basic equation.
- S = the total number of people between the ages of 6 and 19 in each statistical unit inside 2500 feet
- Fn = the average weekly attendance inside 2500 feet

The model applied in this form estimated the core user group to be approximately 54% of the total user population which was quite close to the figure established in the original sample.

2 The Peripheral User Group -

The peripheral user group does not appear to satisfy the conditions set forth in the core user group and to use the same equation without introducing additional variables would be an unrealistic situation. The following additional variables were included:

1. The income effect -

The rate of patronage was observed to be inversely proportional te

the income for the paperation outside 2000 feet. In other words, low income groups had a greater tendency to use the facility than high income groups. As a result, the final value for a statistical unit outside the core user group was multiplied by the average income of all the statistical units divided by the actual income of the statistical unit under investigation. This approach had the tendency to either increase or decrease the attendance. For example; if the average income of all the units was 4000 dollars, and the average income of the statistical unit under analysis was 3000 dollars, the final attendance figure would be increased by approximately 1/3.

4000 (3000 X final no. of probable users)

2 Establishing a K Value -

Some constant had to be developed to take into account the remaining variation. By trial and error, a constant was applied to the outside equation in the hopes that the final answer would be close to the desired result. The value for K that came closest to estimating the total peripheral attendance was 2.755. The outside equation thus took the form:

j = K(P.S.Fk.Inc)

where:

j = the total attendance outside
 2500 feet at swimming pool j.
K = some constant to be estimated
 by trial and error.
P = the probability values obtained
 by the basic equation.

10)

- a = the lotel number of people be tween the ages of 6 and 19 in each statistical unit outside 2500 feet.
- Fk = the average weekly attendance
 of the peripheral user group.
 Inc = the income effect (average in-

come divided by the actual

income

Step 7:

Estimating the Total Average Weekly Attendance

After having accounted for irregularities in the surface demand potential by the consideration of additional variables, the next step was to estimate the total average weekly attendance. This was found by application of the behavioral model in its final form. In this instance, the total expected attendance is found by summing the core and peripheral user demand. The equation thus took the form:

j = (P.S.Fn) + K(P.S.Fk.Inc)

where:

j = the total expected attendance at
 swimming pool j

For computer purposes, the equation takes the form:

$$(cij) = \begin{pmatrix} (\frac{j}{D_{1}}) \\ n = 4 \\ \sum_{j=21}^{n} (\frac{s_{j}}{D_{j}}) \\ j = 21 \end{pmatrix} + K \begin{pmatrix} (\frac{j}{D_{1}}) \\ n = 4 \\ \sum_{j=229}^{n} (\frac{s_{j}}{D_{j}}) \\ j = 229 \end{pmatrix} + 10^{2}$$

wheret

The number of statistical units within the core user group was 21 and the number of units in the peripheral user group was 229. The computer model as it exists calculated a total average weekly attendance of $3_{9}039$ for Lanspeary pool while the actual average weekly attendance based on the past five years was 2,798. The model thus calculated the average weekly attendance with greater than 92 per cent accuracy or within 8 per cent of the actual attendance.

In an attempt to further establish the accuracy of the model's predictive capabilities, it was applied to Atkinson pool in the northwest part of the city using the same constant developed for Lanspeary. The attendance for Atkinson was estimated to be 2,288 while the actual attendance was an average of 2,473. Again this estimate was greater than ninety-two percent accurate and within 8 per cent of calculating the actual average weekly attendance.

It is possible the model could be even more accurate by incorporating additional relevant variables. However, the model should not

<u>10 Note:</u> All the symbols used in this equation are as previously defined.

contain so many variables that it becomes unmanageable in terms of practical application. The model in its present form was able to estimate with a high degree of accuracy the attendance of Lanspeary and Atkinson pools in less than one minute using a 1620 computer. This perhaps attests to its reliability and efficiency as a planning instrument.

The model as it exists is capable of:

- 1 Estimating present and future demands for swimming by taking into account changes in the characteristics of the population. In this way future planning can be a meaningful concept.
- 2 The model can determine the proper location of a swimming poel in terms of the greatest user satisfaction. The best alternative for location is where the facility will receive the greatest attendance thus fulfilling the supply side of the problem.
- 3 It makes full use of the internal dependencies of the system whereby when one input changes, the other inputs also change in response to the original stimulus. The model is thus easily adapted to a variety of conditions that are susceptible to changes through time.
- 4 The model is simple, easily interpreted, accurate, and readily adaptable to a variety of recreation problems; particularly with regard to the location problem where supply and demand achieve reality.
- 5 The model is capable of determining the proper size a facility should be at a specific location. This is accomplished by having the size variable the only unknown in the equation.

To summarize, the analysis should proceed through the following stages:

- 1 Identification of the problem and selection of the necessary variables relevant to a solution by examination of the system and its interactions.
- 2 Testing the variables chosen using a multiple correlation analysis.
- 3 Division of the study area into a grid of functional statistical units.
- 4 Establishing the surface demand potential for each of the recreation facilities under investigation using the basic gravity model.
- 5 Accounting for the irregularities in the pattern of demand by the inclusion of additional variables.
- 6 Summing up total demand for the recreation facility under analysis and determining whether they are properly located, if more are needed, where they should be located and what trends are presently taking place so that accurate future planning might take place.

CHAPTER V

CONCLUSION

Although the model has been developed for the analysis of swimming pools in the city of Windsor, the basic inputs should be similar to conditions that might exist in other cities. These inputs can be tested by applying the model in its existing form and if the desired results do not vary by any great degree, the model is suitable for application. However, if the model does not function with the desired degree of accuracy it may be necessary to examine any other variables that might be relevant to the new study area. If no new variables are readily apparent, all that might have to be changed is the value for the constant. This adjustment might compensate for any slight changes in the variables that might have been necessary.

The Approach And Its Usefulness:

The emphasis of the analysis is on the populations that make use of the facility. This represents the demand side of the problem. Only through the analysis of this demand can the supply side of the problem be fulfilled. This is accomplished by locating the required facilities in those areas that will most adequately fulfill the demand. The demands of populations change through time and by analysis of the "system", these changes can be noted. Only when the inter relationships of all the variables are understood, is it possible to develop a model

capable of demonstrating these inter relationships. It is hoped that the "system" developed in this paper has provided some insight into this aspect of recreation planning.

Although the usefulness and accuracy of the approach has been demonstrated by the analysis of only one particular type of recreation activity, it is hoped that this single demonstration represents an indication of its potential use as a reliable instrument for the analysis of a variety of recreation - location problems. It is likely that the basic gravity model approach is suitable to the regional as well as the urban or local environment. However, before attempting such an analysis it would be necessary to examine closely the different conditions that might exist. An interesting application might be the analysis of regional parks to determine if the variables in planning for this type of recreation facility exist under the same conditions as those for local swimming pools. It is likely that some changes would have to be made although the relationships of size, distance and competition would probably remain the same. Such a model might be developed to establish the best alternatives for the location of additional regional parks, how large they should be, what facilities should be included and what the expected attendance is likely to be. The Implications of The "Double Universe" Approach:

The model in its basic form eliminates rigid boundary lines in terms of "market" areas and substitutes probability lines, radiating outward from the facility under examination. This approach gives a "best" estimate of the expected attendance - a concept presently being accepted

.

as a realistic improvement over the methods employed by some marketing and location experts. I have altered this approach in my analysis such that there is a double universe concept — a concept that treats separately a "core", and a "peripheral" market area. Both groups are treated as "probable" markets for recreation facilities with special treatment of each universe to compensate for any differences that might exist between them. There is no definite boundary line between each universe although some decision must be made by the analyst to separate them. This decision is based upon a sample distribution of the populations that make use of the facility and in this way a realistic simulation of real world conditions can be established. It is hoped that this has been an important contribution to the understanding and treatment of market areas in location analysis in general.

The Quantitative Approach And The Geographer

It might be noted that the dangers involved in model building and the quantitative approach, lay in the possibility of over simplifying problems in order to keep the analysis in workable form. It is hoped that this has not been the case for the model I have developed. Even though quantitative analysis makes no pretense at accounting for some factors and does not include intangible and human values, it may offer more evidence than personal judgement in a decision making situation. When criteria and values are valid and when models are good predictors, decisions based on them are justified. On the other hand, when criteria and values are vague, and when quantitative aspects of the model can only account for a small portion

of the problem, decisions must rely heavily upon judgement and experience.

Although no apologies are necessary for the approaches geographers have taken in the past, there appears to be an increasing reliance upon the use of quantitative analysis and models designed to aid the geographer in his research. This perhaps represents one of the most exciting developments within the field of Geography and shall continue to be welcomed by any geographer who understands these advances in the light they deserve. This is particularly true of the location geographer. However, it must be understood that such techniques still remain the servants and not the masters of the decision making process.

APPENDIX II

AVERAGE WEEKLY ATTENDANCE

BXPECTED AT LANSPEARY POOL

- S = the total number of people in each statistical unit.
- P = the probability value for each statistical unit using the basic gravity model.
- S*P = the probable number of visitors from each statistical unit that are likely to go swimming at Lanspeary.
- S*P*FN = the average expected weekly attendance for each statistical unit inside 2500 feet (core user group).
- S*P*FK = the average expected weekly attendance for each statistical unit outside 2500 feet (peripheral user group).
- Inc = the final expected attendance for the peripheral user group for each statistical unit (the peripheral user group).

APPENDIX III

AVERAGE WEEKLYATTENDANCE AT ATKINSON SWIMMING POOL

- S = the total number of people in user group in each statistical unit.
- P = probability value for each statistical unit using the basic gravity model.
- S*P = the probable number of visitors from each statistical unit that are likely to go swimming at Atkingon.
- S*P*FN = the average expected attendance for each statistical unit inside 2500 feet (core user group).
- S*P*FK = the average expected attendance for each statistical unit outside 2500 feet (peripheral user group).
- Inc = the final expected attendance for the peripheral user group for each statistical unit (the income effect).
